Why are the delays in the AM peak hour so different between $192^{\text {nd }}$ and Jaguar when they have similar volumes? $192^{\text {nd }}$ Street is a 4-leg intersection while Jaguar Ave is a T-intersection. So when turning (especially when turning left) at $192^{\text {nd }}$ Street from one of the side streets, the vehicles may have to not only wait for an appropriate gap, but yield to an opposing vehicle turning left or going straight. For example, there are 90 southbound vehicles turning left at $192^{\text {nd }}$ Street in the peak hour, and vehicles turning left from the school driveway have to yield to these vehicles.

## MODEL RESULTS

## Results of Modeling Jaguar Avenue

Seconds)
*Future Scenario assumes local street connection to Ipava.
Why are the delays at Jaguar generally the same with and without a signal at $192^{\text {nd }}$ when the gapping data shows differences? There are two measures associated with gaps. First, how many are there. Second, how many vehicles can be served. While the number of gaps changes as well as the number of vehicles that can be served, the vehicles that can be served is well above the demand volume. In the videos it illustrates that there is a difference in delay for some vehicles. However, some vehicles wait less, others have to wait more. So by the time these differences are averaged over 10 model runs, the intersections operate about the same for the two scenarios.

## MODEL RESULTS

## How do the proposed changes in access and roadway cross-section compare?

| Performance Measures |  | EXISTING | EXISTING WITH IMPROVED SIGNAL AT CH 60 | EXISTING WITH ROUNDABOUT AT CH 60 | EXISTING WITH ROUNDABOUT AT CH 60 \& SIGNAL AT 192 ${ }^{\text {ND }}$ | EXISTING WITH ROUNDABOUT AT CH 60 \& FOUR-LANES | FUTURE |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
